Abstract. With the increase in computational power, ocean models with kilometer-scale resolution have emerged over the last decade. These models have been used for quantifying the energetic exchanges between spatial scales, informing the design of eddy parametrizations and preparing observing networks. The increase in resolution, however, has drastically increased the size of model outputs, making it difficult to transfer and analyze the data. Nonetheless, it remains of primary importance to assess more systematically the realism of these models. Here, we showcase a cloud-based analysis framework proposed by the Pangeo Project that aims to tackle such distribution and analysis challenges. We analyze the output of eight submesoscale-permitting simulations, all on the cloud, for a crossover region of the upcoming Surface Water and Ocean Topography (SWOT) altimeter mission near the Gulf Stream separation. The models used in this study are run with the NEMO, CROCO, MITgcm, HYCOM, FESOM and FIO-COM code bases. The cloud-based analysis framework: i) minimizes the cost of duplicating and storing ghost copies of data, and ii) allows for seamless sharing of analysis results amongst collaborators. We describe the framework
and provide example analyses (e.g., sea-surface height variability, submesoscale vertical buoyancy fluxes, and comparison to predictions from the mixed-layer instability parametrization). Basin-to-global scale, submesoscale-permitting models are still at their early stage of development; their cost and carbon footprints are also rather large. It would, therefore, benefit the community to document the different model configurations for future best practices. We also argue that an emphasis on data analysis strategies would be crucial for improving the models themselves.

1 Introduction

Traditionally collaboration amongst multiple ocean modelling institutions and/or the reproducing of scientific results from numerical simulations required the duplication, individual sharing and downloading of data, upon which each party of interest would analyze the data on their local workstation or cluster. We will refer to this as the ‘download’ framework (Stern et al., 2022). As realistic ocean simulations with kilometric horizontal resolution have emerged (e.g., Rocha et al., 2016; Brodeau et al., 2020; Gula et al., 2021; Ajayi et al., 2021), such a framework has become cumbersome with tera- and peta-bytes of data needed to be transferred and stored as ghost copies. Nevertheless, a real demand exists for collaboration to inter-compare models to examine their fidelity and quantify robust features of submeso- and meso-scale turbulence (the former on the horizontal spatial scales of $O(10\text{km})$ and latter on $O(100\text{km})$; here on referred to jointly as (sub)mesoscale; Hallberg, 2013; McWilliams, 2016; Lévy et al., 2018; Uchida et al., 2019; Dong et al., 2020). The Ocean Model Intercomparison Project (OMIP), for example, has been successful in diagnosing systematic biases in non-eddying and mesoscale-permitting ocean models used for global climate simulations (Griffies et al., 2016; Chassignet et al., 2020).

Here, we would like to achieve the same goal as OMIP but by inter-comparing submesoscale-permitting ocean models, which have been argued to be sensitive to grid-scale processes and numerical schemes as we increasingly push the model resolution closer to the scales of non-hydrostatic dynamics and isotropic three-dimensional (3D) turbulence (Hamlington et al., 2014; Soufflet et al., 2016; Ducousso et al., 2017; Barham et al., 2018; Bodner and Fox-Kemper, 2020). Considering the enormous computational cost and carbon emission of these submesoscale-permitting models, it would also benefit the ocean and climate modeling community to compile the practices implemented by each modeling group for future runs. In doing so, we analyze eight realistic, submesoscale-permitting ocean simulations, which cover at least the North Atlantic basin, run with the code bases of the Nucleus for European Modelling of the Ocean (NEMO; Madec et al., 2019, https://www.nemo-ocean.eu/), Coastal and Regional Ocean COmmunity model (CROCO; Shchepetkin and McWilliams, 2005, https://www.croco-ocean.org/), Massachusetts Institute of Technology general circulation model (MITgcm; Marshall et al., 1997, https://mitgcm.readthedocs.io/en/latest/), HYbrid Coordinate Ocean Model (HYCOM; Bleck, 2002; Chassignet et al., 2009, https://www.hycom.org/), Finite volumE Sea ice-Ocean Model (FESOM; Danilov et al., 2017, https://fesom2.readthedocs.io/en/latest/index.html), and First Institute of Oceanography Coupled Ocean Model (FIO-COM, http://fiocom.fio.org.cn/). Considering the amount of data, however, the download framework becomes very inefficient. Therefore, we have implemented the ‘data-proximate computing’ framework proposed by the Pangeo project where we have stored the model outputs on the cloud and brought the computational resources adjacent to the data on the cloud (Abernathey et al., 2021a; Stern et al., 2022).
Figure 1. SWOT tracks during its calibration phase and strategic Xover regions in the Atlantic sector. The regions cover the Gulf Stream separation and its extension (Regions 1 and 2), western Mediterranean Sea (Region 3) and Agulhas Rings (Region 4).

Many of these simulations were developed ahead of the Surface Water and Ocean Topography (SWOT) satellite launch (Morrow et al., 2019), now projected to be in November 2022, in order to allow for the instrumental calibration of SWOT (Gomez-Navarro et al., 2018; Metref et al., 2020), and to disentangle the internal wave signals from (sub)mesoscale flows; SWOT is expected to observe the superposed field of the two dynamics (Savage et al., 2017a; Torres et al., 2018; Yu et al., 2021). During its calibration phase, SWOT will pass over the same site every day for six months and have tracks that will cross over with each other. In order to showcase the data-proximate computing framework and its potential for collaborative, open-source and reproducible science, we provide example diagnostics for one of the SWOT Crossover (Xover) regions around the Gulf Stream separation (Region 1 in Figure 1). We leave the detailed diagnostics of (sub)mesoscale flows including other SWOT-Xover regions and the potential impact of modeling numerics on the resolved flow for a subsequent paper.

The paper is organized as follows: We describe the data-proximate computing framework in section 2 and showcase some example analyses using this framework in section 3. Cautionary remarks regarding sustainability into the future for open-source reproducible science are given in section 4 and we conclude in section 5.

2 Data-proximate computing framework

In order for the data-proximate computing framework to work for collaborative, open-source and reproducible science, it requires two components to work together simultaneously: i) public access to analysis-ready data, and ii) open-source computational resources adjacent to the data.
2.1 Analysis-ready cloud-optimized data

In the field of Earth Science, model outputs are often archived and distributed in binary, HDF5 or NetCDF formats. While we have greatly benefited from these formats, they are not optimized for cloud storage nor for parallelized cloud computing. However, as Earth Scientists, commonly we do not possess the training in cloud infrastructure nor data engineering required to efficiently convert large scale archival datasets into formats which allow us to leverage the full performance potential of the commercial cloud. Data engineers, on the other hand, do not know the scientific needs of the data. In collaboration with Pangeo Forge (Stern et al., 2022, https://pangeo-forge.readthedocs.io/en/latest/), we have therefore, attempted to fill this niche by streamlining the process of data preparation and submission. To transform their data into analysis-ready cloud optimized (ARCO) formats, data providers (ocean modeling institutions in our case) need only specify the source file location (e.g., as paths on an Ftp, Http or OPeNDAP server) along with output dataset parameters (e.g., particular ARCO format, chunking) in a Python module known as a recipe. The recipe module, which is typically a few dozen lines of Python code, relies on a data model defined in the open source pangeo-forge-recipes package. Once complete, the recipe is submitted via a Pull Request on Github to the Pangeo Forge staged-recipes repository (https://github.com/pangeo-forge/staged-recipes). From here, Pangeo Forge automates the process of converting the data into ARCO format and storing the resulting dataset on the cloud, using its own elastically-scaled cloud compute cluster. The term “analysis-ready” here is used broadly to refer to any dataset that has been preprocessed to facilitate the analysis which will be performed on it (Stern et al., 2022). An example of such recipe for eNATL60 described in section 3 is given in Appendix A. We refer the interested reader to Abernathey et al. (2021a) and Stern et al. (2022) for further details on the technical implementation.

The crowdsourcing approach of Pangeo Forge, to which any data provider can contribute, not only benefits the immediate scientific needs of a single research project, but also the entire scientific community in the form of shared, publicly accessible ARCO datasets which remain available for all to access. This saves each scientist the cost of duplicating and storing ghost copies of the data and allows for reproducible science. The model outputs used for this study are stored on the Open Storage Network (OSN), a cloud storage service provided by the National Science Foundation (NSF) in the U.S. The surface data were saved hourly and interior data in the upper 1000 m as daily averages. To facilitate the access of data from OSN, we have further made them readable via intake, a data access and cataloging system which unifies the API (https://intake.readthedocs.io/en/latest/overview.html). Namely, the API to read and load the data is the same for all of the data used in this project, regardless of its distribution format (e.g., binary, HDF5 or NetCDF), because each of the datasets has been converted by Pangeo Forge into the cloud-optimized Zarr format, and subsequently cataloged with intake, prior to analysis. This is particularly beneficial for our case where we would like to systematically analyze multiple data collections. Jupyter notebooks for the results shown in section 3, including the Yaml file to access data via intake, are given in the Pangeo Data swot_adac_ogcms Github repository (https://github.com/roxyboy/swot_adac_ogcms/tree/notebook; a DOI will be added upon acceptance of the manuscript).
2.2 Cloud-based JupyterHub

For data-proximate computational resources, we have implemented a JupyterHub, an open-source platform that provides remote access to interactive sessions in the cloud for many users (Fangohr et al., 2019; Beg et al., 2021), on the Google Cloud Platform. This infrastructure is run in collaboration with 2i2c.org, a non-profit organization based in the U.S. that manages cloud infrastructure for open source scientific workflows. Authentication for each user/collaborator on the JupyterHub is provided via a white-list of Github usernames, meaning that the hub can be accessed from anywhere and is not tied directly to an institutional account. This has allowed for real-time sharing of Python scripts amongst collaborators and exchanging of feedback on the analytical results we present in section 3. Cloud computing also offers the scaling of resources for improved I/O throughput and optimization of network bandwidth and Central Processing Units (CPUs).

3 Example analyses

The model outputs used for this showcase are from the eNATL60 (Brodeau et al., 2020), GIGATL (Gula et al., 2021), HYCOM50 (Chassignet and Xu, 2017, 2021), FESOM-GS, LLC4320 (Rocha et al., 2016; Stewart et al., 2018), ORCA36 (https://github.com/immerse-project/ORCA36-demonstrator), FIO-COM32, and HYCOM25 (Savage et al., 2017a, b; Arbic et al., 2018) simulations. The detailed configuration of each simulation is given in Appendix B. In order to motivate the reader on the necessity of inter-comparing realistic submesoscale-permitting simulations, we show in Figure 2 the relative vorticity normalized by the local Coriolis parameter on February 1, 00:00 from each model. Despite their similar spatial resolutions, the spatial scales represented vary widely across models. Submesoscale-permitting ocean modeling is in its early stage of development, and each modeling institution is still exploring best practices. Therefore, we did not specify an experimental protocol, as in OMIP, for the model outputs from each institution. Each model uses different atmospheric products and tidal constituents to force the ocean, and the initial conditions and duration of spin up all vary (Appendix B). Nevertheless, we should expect statistical similarity in the oceanic flow at the spatial scales of $O(10\text{ km})$ if the numerics are robust.

3.1 Surface diagnostics of the temporal mean and variability

In light of the SWOT mission, the primary variable of interest is sea-surface height (SSH), also known as Absolute Dynamic Topography (ADT). SSH is defined as the geodetic height of the sea surface above the reference ellipsoid, while ADT is defined relative to the geoid, but in models where the geoid and reference ellipsoid coincide these two definitions are in practice the same (Gregory et al., 2019). From an ocean modelling perspective, one of the key features to argue in favor of increasing resolution has been the improvement in representing the Gulf Stream (GS) separation (Chassignet and Xu, 2017, 2021). In assessing the models, it is common to examine the mean state, which we define as the time mean, and variability about the mean. From the perspective of computational cost, the time mean of surface fields is the lightest as the reduction in dimension allows for the download framework where the collaborators can share the averaged data. Variability about the time mean requires access to the temporal dimension, making the computational and data storage cost intermediate. We will further show
Figure 2. A snapshot of surface relative vorticity normalized by the local Coriolis parameter on February 1, 00:00 from each model in Region 1.
in section 3.2 an example of 3D diagnostics of the submesoscale flow, which significantly increase the computational cost and burden of transferring data; this will highlight the strength of the data-proximate framework where we can consistently apply the same diagnostic methods across different datasets.

In Figure 3, we show the time mean and temporal standard deviation of SSH from the eight models in the GS separation region. We also show the time-mean ADT from the Archiving, Validation and Interpretation of Satellite Oceanographic (AVISO) data for reference. We do not show the standard deviation for AVISO as the spatiotemporal interpolation and smoothing limit its effective resolution to $O(100 \text{ km})$ and $O(10 \text{ day})$ (Chelton et al., 2011; Arbic et al., 2013; Chassignet and Xu, 2017). We provide the standard deviations of SSH filtered in a manner similar to the smoothing that goes into the AVISO products in Appendix C. The GS in most models tend to separate off of Cape Hatteras on the east coast of the U.S. consistent with AVISO (Figure 3a,c,g,i,k,o,t). In terms of the magnitude of mean SSH, HYCOM50 may be overestimating it relative to AVISO across the path of the separated Gulf Stream. The GS in LLC4320 tends to separate relatively southwards while in FESOM-GS separates northwards relative to AVISO observations respectively (Figure 3e,i). The separation in FESOM-GS may be closer to the observed state in 2014 (Figure 3s) rather than 2012, the actual year of model output. Regarding the standard deviation, while expected, it is interesting that the simulations without tides (FESOM-GS and ORCA36; Figure 3f,l) show significantly lower temporal variability compared to the other models. Although HYCOM25 is tidally forced, its standard deviation is relatively low (Figure 3p), which may be due to lower spatial resolution than the region- and basin-scale models used here (Table A3), the computational tradeoff of it being a global simulation. HYCOM25 nevertheless has higher values than FESOM-GS and ORCA36. Considering the difference between simulations tidally forced and not, it is likely that in order to emulate the upcoming SWOT observations, applying tidal forcing is a key aspect in addition to model resolution (Savage et al., 2017a, b; Arbic et al., 2018).

To complement the temporal standard deviation, in Figure 4, we show the frequency spectra of SSH in the GS separation region. The frequency periodograms were computed every $\sim 10 \text{ km}$ using the \texttt{xrft} Python package (Uchida et al., 2021) and then spatially averaged to compute the spectra. The temporal linear trend was removed and a Hann window was applied prior to taking the Fourier transform of SSH as commonly done in studies examining spectra (e.g., Uchida et al., 2017; Savage et al., 2017a; Khatri et al., 2021). At frequencies higher than the Coriolis frequency, LLC4320 shows the highest variability and FESOM-GS the lowest. FIO-COM32 shows the largest spectral amplitudes at the diurnal and semi-diurnal frequencies amongst the models, which reflects itself in the large standard deviation (Figure 3n). LLC4320 also shows the largest number of spectral peaks at tidal frequencies, likely due to being forced with the largest number of tidal constituents amongst the models used here (Table A5). It is not surprising that FESOM-GS lacks spectral peaks at diurnal and semi-diurnal frequencies, considering that it is not tidally forced. ORCA36, on the other hand, although not tidally forced displays some activity at diurnal and semi-diurnal frequencies. However, the lower peaks at tidal frequencies in ORCA36 compared to the tidally forced runs reflect themselves in the lower standard deviation as seen in Figure 3l. eNATL60, GIGATL, HYCOM50 and HYCOM25 show similar levels of variability in the diurnal and semi-diurnal band. At time scales longer than 10 days, ORCA36 tends to show the highest variance while HYCOM25 shows the lowest.
Figure 3. The temporal mean and standard deviation of SSH in the Gulf Stream separation region (Region 1) during the months of February, March and April using hourly outputs. The bottom row shows the seasonal mean of ADT fields from AVISO during the months of February, March and April. Daily AVISO data were used to compute the seasonal mean for three individual years (2011, 2012 and 2014) and over 2010-2018. The spatial mean is subtracted from the temporal mean fields from the models and AVISO to ensure that the mean SSH/ADT anomaly fields are comparable (i.e., large-scale steric contributions have been removed).
Figure 4. The frequency spectra of hourly SSH for winter (February, March, April; left) and summer (August, September, October; right). The frequency periodograms were computed every $\sim 10$ km in Region 1 and then spatially averaged. The runs without tidal forcing (FESOM-GS and ORCA36) are shown in dashed lines. The Garrett-Munk spectral slope of $\omega^{-2}$ (Garrett and Munk, 1975) is shown as the grey solid line and the domain-averaged Coriolis frequency as the grey dashed line.

3.2 Three-dimensional diagnostics on physical processes

To exemplify 3D diagnostics, we display the submesoscale vertical buoyancy flux from each model. Submesoscale vertical buoyancy fluxes in the surface ocean have been of great interest to the ocean and climate modeling community as they modulate the air-sea heat flux, affect mixed-layer depth (MLD), and are a proxy for baroclinic instability taking place within the mixed layer (often referred to as mixed-layer instability (MLI); Boccaletti et al., 2007; Mensa et al., 2013; Johnson et al., 2016; Su et al., 2018; Uchida et al., 2017, 2019; Schubert et al., 2020; Khatari et al., 2021). Ocean models used for climate simulations, however, lack the spatial resolution to resolve MLI due to computational constraints. A recent parametrization proposed by Fox-Kemper et al. (2008) has been operationally implemented by multiple climate modeling groups (Fox-Kemper et al., 2011; Huang et al., 2014; Calvert et al., 2020). While the vertical buoyancy flux predicted by the MLI parametrization has been tested in idealized simulations (Boccaletti et al., 2007; Fox-Kemper and Ferrari, 2008; Brannigan et al., 2017; Callies and Ferrari, 2018), non-eddying and mesoscale-permitting coupled and ocean-only simulations (Fox-Kemper et al., 2011; Calvert et al., 2020), and single-model assessments (e.g., Mensa et al., 2013; Li et al., 2019; Yang et al., 2021; Richards et al., 2021), to our knowledge, a systematic assessment of the MLI parametrization has not been done versus multi-model, submesoscale-permitting, realistic ocean simulations which at least partially resolve the flux in need of parametrization in climate simulations. We take advantage of the unique opportunity provided by our collection of simulations to assess the flux parametrization, i.e.,
the covariance of the 3D vertical velocity and buoyancy fields versus the modeled mixed layer depth and horizontal buoyancy gradient (3D data were not available for the HYCOM25 simulation).

The MLI parametrization predicts that the submesoscale vertical buoyancy fluxes vertically averaged over the mixed layer $\langle \cdot \rangle_z$ can be approximated by the squared horizontal gradient of the mesoscale buoyancy field times the mixed layer depth squared:

$$w^s b^s \propto \frac{H_{\text{ML}}^2 |\nabla_h b^m|^2}{|f|},$$

(1)

where $w$, $b$, $f$ and $H_{\text{ML}}$ are the vertical velocity, buoyancy, local Coriolis parameter and MLD. While each model used a different Boussinesq reference density ($\rho_0$), buoyancy was defined as $b = -g \frac{\sigma_0}{\rho_0}$ where $\sigma_0$ is the potential density anomaly with the reference pressure of 0 dbar and $\rho_0 = 1000$ kg m$^{-3}$ for all model outputs. The MLD was defined using the density criterion (de Boyer Montégut et al., 2004), viz. the depth at which $\sigma_0$ increased by 0.03 kg m$^{-3}$ from its value at $\sim 10$ m depth. $\nabla_h$ is the horizontal gradient and the superscripts $s$ and $m$ indicate the submeso- and meso-scale field respectively. The decomposition between the two were done by applying a Gaussian filter with the standard deviation of 30 km using the gcm-filters Python package (Grooms et al., 2021). Namely, the mesoscale field is defined as the spatially smoothed field with the Gaussian filter and submesoscale as the residual $\langle \cdot \rangle^s = \langle \cdot \rangle - \langle \cdot \rangle^m$. The $b^m$ field includes scales larger than the typical mesoscale but as it is the horizontal gradient of this field we are interested in, $\nabla_h b^m$ captures the mesoscale fronts. We note that the Gaussian filter, implemented as a diffusive operator, commutes with the spatial derivative (this is an important property as we take the horizontal gradient of $b^m$; Grooms et al., 2021). While we acknowledge that there may be more sophisticated methods to decompose the flow (Uchida et al., 2019; Jing et al., 2020; Yang et al., 2021), a spatial filter has been commonly applied in examining the submesoscale flow in realistic simulations (e.g., Mensa et al., 2013; Su et al., 2018; Li et al., 2019; Jing et al., 2021). Recently, Cao et al. (2021) argued that in addition to spatial cutoffs, a temporal cutoff improves the decomposition. Upon examining the frequency-wavenumber spectra of relative vorticity and horizontal divergence, however, we found that the daily averaging effectively filtered out the internal gravity waves (not shown). Based on characteristic time scale arguments, it is likely that our daily-averaged submesoscale fields are capturing the component in balance with stratification and Earth’s rotation (Boccaletti et al., 2007; McWilliams, 2016), although some of the submesoscale balanced variability and nearly all of the internal gravity wave variability is filtered out by the daily average. Figure 5 shows the decomposition for $w$ and $b$ from eNATL60 on February 1, 2010 at depth 18 m. We see the characteristic feature of the Gulf Stream separation particularly in the buoyancy field (Figure 5d) and submesoscale fronts (Figure 5c,f) superimposed on top of the large scale flow (Figure 5b,e). We will focus on the late winter/early spring months (February, March and April) as the spatial scale of MLI during summer is not well resolved even at kilometric resolution (February, March and April) as the spatial scale of MLI during summer is not well resolved even at kilometric resolution (Dong et al., 2020). We also restrict our diagnostics to the open ocean where the bathymetry is deeper than 100 m (e.g., Figure D1).

Considering that the Fox-Kemper et al. (2008) MLI parametrization is intended for mesoscale-permitting models (neglecting the dependency on model grid-scale: $\Delta s$ in Fox-Kemper et al., 2011), we further coarse grained the fields to $\sim 1/12^\circ$ with a
Figure 5. Snapshot from eNATL60 on February 1, 2010 at depth 18 m of the unfiltered daily \( w \) and \( b \) (left column), filtered fields applying the Gaussian filter \( (w^m, b^m) \) (middle column), and the residual \( (w^s, b^s) \) (right column).

The box-car operator, which gives:

\[
\left\langle \frac{w^s b^s}{b^s} \right\rangle \simeq C_e |f|^{-1} \left( \int_{H_{ML}} 0 \langle |\nabla b^m| \rangle dz \right)^2,
\]

where \( \langle \cdot \rangle \) is the coarse-graining operator and \( C_e \) a tuning parameter (Fox-Kemper et al., 2011), or 'efficiency coefficient'. We diagnosed \( C_e \) by taking the ratio between the right-hand and left-hand side of equation (2) at each grid point and time step, and then the horizontal spatial median of it. The diagnosis (2) would differ from the parametrization (1) if there are large vertical variations in the buoyancy gradient, but these are not expected within the frequently-remixed mixed layer. Furthermore, the efficiency coefficient is expected to vary among the multi-model ensemble according to how well-resolved and/or damped the submesoscale instabilities are by model numerics, sub-grid schemes, and daily averaging.

The diagnosed \( C_e \) only has a time dependence and fluctuates between the range of \([0.01, 0.07]\) across most models (blue solid curves in Figure 6) in agreement with the value of 0.06 recommended by Fox-Kemper et al. (2008). The order of magnitude of the spatial median of the submesoscale vertical buoyancy flux diagnosed from the models \( (O(5 \times 10^{-9} \text{ m}^2 \text{ s}^{-3})) \) also agrees with observational estimates (Mahadevan et al., 2012; Johnson et al., 2016; Buckingham et al., 2019) with an overall decrease in
amplitude towards May except for FIO-COM32, which shows a local maximum around March (black solid curves in Figure 6). The spatial field of both sides of equation (2) on February 1 for each model are given in Figure D1. Other than the time series of the spatial median of $\langle w^s b^z \rangle$ and its prediction from the MLI parametrization being in sync with each other (black and red solid curves in Figure 6), the joint histograms of the two are concentrated around the one-to-one line indicating spatial correlation (Appendix D). For operational purposes, we would like to have a tuning parameter that is independent of not only space but also time. Therefore, we also display the MLI prediction when $C_e$ is a constant taken to be its time mean. The agreement between $\langle w^s b^z \rangle$ and the prediction remains surprisingly good (red dashed curves in Figure 6); in other words, the MLI parametrization is relatively insensitive to the temporal variability of $C_e(t)$. Regarding inter-model differences, HYCOM50 and LLC4320 have the smallest buoyancy fluxes predicted by the MLI parametrization (i.e., weaker horizontal gradient magnitude and/or shallower mixed layer depths). This presents itself as $C_e$ diagnosed from the two taking an order of magnitude larger values than the other models (blue curves in Figure 6c,e); particularly for HYCOM50, using a constant $C_e$ fails to reproduce the magnitude of $\langle w^s b^z \rangle$ during the early half of February (red dashed curve in Figure 6c). It is possible that the lowest vertical resolution of HYCOM50 amongst the models (Table A3) results in under-representing the MLD despite its fine horizontal resolution particularly south of the Gulf Stream (Figure D2c); the MLI parametrization depends on it quadratically (equation (1)). The MLD from LLC4320 is also relatively shallow (Figure D2e). HYCOM50 and LLC4320 both use the K-profile parametrization (KPP, Table A2; Large et al., 1994) for the boundary-layer closure, which may imply that the KPP parameters warrant further tuning or reformulation for submesoscale-permitting model resolutions (e.g., Bachman et al., 2017; Souza et al., 2020). The shallow MLD may also be due to the differences in the atmospheric products used to force the models (Table A5).

4 Conditions for sustainability

The strength of cloud storage and computing comes from it being decentralized from any specific institution, but this also leaves open the question about who pays for the cost of operating and supporting the cloud infrastructure, as well as paying for the cloud resources. Currently as of writing, the cloud storage provided by OSN is funded by an NSF grant acquired by the Climate Data Science Laboratory at Columbia University, and the JupyterHub on Google Cloud Platform by Centre National d’Études Spatiales (CNES) funding. The cost of cloud resources for the JupyterHub with parallelized computation adds up to roughly 1000 € per month with the maximum computational resources of 64 cores and 256 gigabytes of memory per user; the resources scale on-demand, while the cost of operating the scalable Kubernetes infrastructure is managed by a vendor (2i2c) for a few thousand dollars a month. Although this may seem expensive compared to the local download framework where the costs of computation on clusters are shouldered upfront upon purchase of the cluster, there are several benefits to a cloud-based approach. First, using cloud infrastructure shifts the burden of hardware maintenance to the cloud provider, and users benefit from regular updates to technology and services that are available, meaning the scientific community can benefit from industry-driven innovations. Second, cloud infrastructure can be managed remotely and may use a standard stack that is supported by many cloud providers (such as open source tools like Kubernetes and JupyterHub), making it easier to port workflows between clouds and get more cost-effective support in operating this infrastructure compared with paying full-time
Figure 6. Time series of the spatial median of the submesoscale vertical buoyancy flux averaged over the MLD \( \langle \omega b z \rangle \); black solid curve) and its prediction from the MLI parametrization during the months of February to April. The prediction with temporally varying \( C_e(t) \) is shown in red solid curves and with a temporally averaged (constant) \( C_e \) in red dashed curves. \( C_e(t) \) is plotted against the right y axes in blue. Three-dimensional data were not available for HYCOM25.
employees that run local hardware for an institution. As the cloud-based framework spreads within the scientific community, it is also possible that the ocean and climate science community will be able to negotiate better deals with cloud service providers; the framework is apt for Ocean and Climate Model Intercomparison Project (OMIP and CMIP) type studies where tera- and peta-bytes of data need to be shared and analyzed consistently. The systematic storage of ARCO data with open access will also enable reproducible science, a crucial step when evaluating newer simulations against previous runs. While we believe we have showcased the potential for cloud-based computing, the success of the framework will depend on the scientific community to convince its peers and funding organizations to recognize its benefit.

5 Conclusions

In this study, we have implemented a cloud-based framework for collaborative, open-source and reproducible science, and have showcased its potential by analyzing eight submesoscale permitting simulations at a SWOT Crossover (Xover) region around the Gulf Stream separation (Region 1 in Figure 1). We have shown that despite the similar horizontal resolution amongst many models in this study, the spatial scales represented vary widely (Figure 2). This diverse representation likely originates from differences in advective/diffusive schemes, boundary layer parametrizations, atmospheric and tidal forcing, vertical resolution and/or bathymetry amongst the simulations used here (Appendix B; cf. Chassignet and Xu, 2021). The need for collaborative work to inter-compare realistic simulations stems from both a scientific interest in the fidelity of submesoscale-permitting ocean models in representing the underlying physics and tracer transport, and an engineering perspective on the numerics of ocean models. We leave a detailed analysis on the impact of numerics on the resolved dynamics for future work.

We have provided example diagnostics on SSH variability and submesoscale vertical buoyancy fluxes. The temporal standard deviation and spectra of SSH were significantly lower for the simulations without tidal forcing compared to the tidally forced simulations (Figures 3 and 4). This implies that in order to emulate the upcoming SWOT altimetric observations, tidal forcing is a key factor in modeling the surface ocean (Savage et al., 2017a, b; Arbic et al., 2018; Yu et al., 2021; Barkan et al., 2021; Le Guillou et al., 2021). Regarding 3D diagnostics, both the good agreement across multiple models between the tuning parameter $C_{\text{e}}$ in the MLI parametrization and the values recommended by its developers (Figure 6; Fox-Kemper et al., 2008; Fox-Kemper and Ferrari, 2008), and the consistency of the order of magnitude of the flux predicted by the parametrization with observational estimates (cf. Richards et al., 2021), combine to provide confidence in implementing the MLI parametrization in realistic ocean and climate models. This is in contrast, however, with a recent study by Yang et al. (2021, their Figure 7) where they found (using the Regional Ocean Modeling System, ROMS with KPP) that the time series of $\langle w_s b z \rangle$ did not correlate well with the prediction from its parametrization in the Kuroshio extension. While we lack access to their model outputs, we speculate that the differences could be due to the diagnostic methods, domain of interest and/or configuration of their simulation. The contrasting findings all the more highlight the need for collaborative and open data analysis strategies of multi-model ensembles in assessing and improving the simulations themselves. We would like to note that were the modeled domain by Yang et al. (2021) covered Region 1, the cloud-based framework would allow for a straightforward platform to extend the ensemble of simulations (Appendix B) to include their outputs for our inter-comparison and reproducible science.
We end by noting that cloud-based data-proximate computation provides a framework to analyze tera- and peta-bytes of data as we further increase the resolution and complexity of ocean and climate simulations, and as SWOT data becomes available. However, the success of the framework will depend on the ability of scientists to convince funding organizations to recognize its potential. Cloud-based computing differs from the conventional workflow which involves funding local computational resources and storage. While the cloud-based framework does not allow for an individual researcher or group to have prioritized access over the data and analytical tools, we believe that open access to the data will allow for reproducible science and facilitate international collaboration.

Code and data availability. The model outputs from eNATL60, GIGATL, HYCOM50, FESOM-GS, ORCA36, FIO-COM32 and HYCOM25 at the SWOT-Xover regions are all publicly available on the Open Storage Network (OSN). The Jupyter notebooks and Yaml file used to access and analyze the data are available on Github (https://github.com/roxyboy/swot_adac_ogcms/tree/notebook; a DOI will be added upon acceptance of the manuscript). The LLC4320 data were accessed via the NASA ECCO Data Portal (https://data.nasa.gov/ecco/data.php?dir=deccodata/llc_4320) using the llcreader of the xmitgcm Python package (Abernathey et al., 2021d; Abernathey, 2019).

Appendix A: Example of pangeo_forge_recipe for eNATL60

Here we provide the Pangeo Forge recipe used to flux eNATL60 surface hourly data to OSN for Region 1 during February and April, 2010. The input_url_pattern is where the original NetCDF files were hosted on an OPeNDAP server, upon which the files were chunked along the time dimension before being fluxed to the cloud in Zarrified format (Miles et al., 2020). As a contributor to Pangeo Forge, one essentially only needs to specify the input_url_pattern. The zarrification and fluxing of the data to the cloud is automated by Pangeo Forge, reducing the infrastructure and cognitive burden on the data provider (Stern et al., 2022).

Listing 1. eNATL60 example

```python
from itertools import product

import pandas as pd
from pangeo_forge_recipes.patterns import pattern_from_file_sequence
from pangeo_forge_recipes.recipes import XarrayZarrRecipe

regions = [1]
season_months = {
    "fma": pd.date_range("2010-02", "2010-05", freq="M")
}

url_base = (
```
def make_recipe_surface(region, season):
    input_url_pattern = url_base + "Surface/eNATL60/Region{reg:02d}/surface-hourly_{ym}.nc"
    months = season_months[season]
    input_urls = [
        input_url_pattern.format(reg=region, ym=date.strftime("%Y-%m")) for date in months
    ]
    file_pattern = pattern_from_file_sequence(input_urls, "time_counter")

    target_chunks = {"time_counter": 72}
    subset_inputs = {"time_counter": 3}
    recipe = XarrayZarrRecipe(
        file_pattern, target_chunks=target_chunks, subset_inputs=subset_inputs
    )

    return recipe

recipes = {
    f"eNATL60/Region{reg:02d}/surface_hourly/{season}" : make_recipe_surface(reg, season)
    for reg, season in product(regions, season_months)
}

Appendix B: Model configurations

We provide the model configurations in Tables A1-A5 (blanks indicate the information was not obtainable). The vertical coordinate transformation onto geopotential coordinates for the outputs of GIGATL and HYCOM50, which had terrain-following and isopycnal coordinates as their native grid respectively (Table A3), were done using the xgcm Python package (Abernathy et al., 2021b) with linear interpolation.

Appendix C: Impact of spatiotemporal smoothing on the temporal standard deviation

In this appendix, we examine the effect of spatiotemporal filtering on the modelled SSH standard deviation. In order to mimic a smoothing procedure similar to the AVISO products, we apply a Gaussian spatial filter with the standard deviation of 50 km using the gcm-filters Python package and a 10 day running mean (cf. Chassignet and Xu, 2017). The non-tidally forced runs do not show much difference upon spatiotemporal smoothing from their standard deviation using hourly outputs but,
they significantly decrease for the tidally forced runs, particularly LLC4320 and FIO-COM32, with the modelled amplitudes coming closer to the AVISO estimate (Figures 3 and C1). The strong reduction in LLC4320 and FIO-COM32 may be expected as they are the runs with highest SSH variance at frequencies higher than the Coriolis frequency (Figure 4). All simulations agree that there is a local maximum in standard deviation around 37°N where the separated GS situates consistent with AVISO. The SSH variability in GIGATL may be on the lower end considering it is tidally forced (Figure C1b).
Appendix D: Joint histogram of submesoscale vertical buoyancy flux

We provide a snapshot of \( \langle w^s b^s \rangle \) and its prediction from the MLI parametrization on February 1 from each model in Figure D1. The joint histograms of the two over the months of February-April are also given in the bottom rows of Figure D1. The slight underestimation of magnitude in the MLI parametrization (viz. values falling below the one-to-one line) comes from the fact that while \( \langle w^s b^s \rangle \) can take negative values locally where frontogenesis dominates (i.e., where the isopycnals steepen), the MLI parametrization by construction cannot differentiate between frontogenesis and frontolysis giving only positive values (equation 1). Nonetheless, \( \langle w^s b^s \rangle \) largely takes positive values indicating that processes such as mixed-layer and symmetric instabilities, which yield positive vertical buoyancy fluxes (Dong et al., 2021), dominate in the surface boundary layer. The MLD averaged between February 1–15 is shown in Figure D2 along with the climatology for the month of February estimated from the Argo floats. We see that the MLD from HYCOM50 and LLC4320 are notably shallower south of the Gulf Stream compared to the other models and Argo estimate.

Figure D1. Snapshot of \((w^n b^s z)\) and \(C_e(t) \times \text{MLI}\) on February 1 for each model. Regions with bathymetry shallower than 100 m are masked out. The bottom row for each model shows the joint histogram of the two during the months of February to April, and the one-to-one line is shown as the grey dashed line. The histograms were computed using the xhistogram Python package (Abernathy et al., 2021c).
Figure D2. MLD from each model averaged over the duration of February 1–15 when the prediction from the MLI parametrization with a constant $C_e$ in HYCOM50 deviates from the diagnosed submesoscale vertical buoyancy flux. The MLD was defined using the density criteria of de Boyer Montégut et al. (2004). For models with non-geopotential vertical coordinates (i.e., GIGATL and HYCOM50), the MLD was computed using their native coordinates respectively. The climatology for the month of February from the Argo floats is taken from the dataset by Holte et al. (2017). The monthly-mean MLD defined by the density criterion ($mld_{dt\_mean}$) is shown in order to be consistent with our model estimates.
